Exercises Unit VIII:
Metropolis algorithm
— to generate gaussian variates
— for importance sampling integration

— verification of the Boltzmann distribution

1. **Random numbers with gaussian distribution: Metropolis algorithm**

   Here we use the Metropolis algorithm to generate points with the distribution $P(x) = e^{-x^2/(2\sigma^2)}$. The algorithm is implemented for instance in the code `gauss_metropolis.f90`. We consider $\sigma = 1$, but the suggestion is to write the code for a generic σ.

   (a) Start from $x_0=0$ and choose $\delta=5\sigma$ to be the maximum displacement for each step. Execute runs with $n=100, 1000, 10000, 100000$ points, make an histogram of the points generated and compare it with the gaussian distribution. For which n the agreement is satisfactory?

   (b) Choose n which gives a satisfactory result. For σ fixed, change the step size δ (i.e., change the ratio δ/σ). Determine qualitatively the dependence of the *acceptance ratio* on δ/σ. Make a plot. How to choose δ/σ in order to accept from $\approx 1/3$ to $\approx 1/2$ of trial changes?

   (c) By varying n in a more refined way (e.g. from 100 to 10000 with steps of 100), compare the first moments of the distribution obtained numerically with the exact ones analytically calculated with the Gaussian. In particular, focus on the second moment and make a plot of the difference "exact variance - numerical variance" as a function of n.

   (d) For fixed $\sigma = 1$ and $\delta=5\sigma$, determine qualitatively the *equilibration time* (i.e. the number of steps necessary to *equilibrate* the system); a possible criterion is that the numerical estimate of $\langle x^2 \rangle - \langle x \rangle^2$ is close enough to σ^2, say within 5%.

2. **Sampling physical quantities with gaussian distribution: direct sampling and Metropolis sampling**

Consider the quantum harmonic oscillator and its ground state. The exact solution and the expectation values of kinetic, potential and total energy are know analytically, and can be used to compare the numerical results.

(a) *Direct sampling.* Estimate kinetic energy, potential energy, first moments $\langle x^i \rangle$ of the wavefunction $\psi(x) = Ae^{-x^2/(4\sigma^2)}$ with a sample-mean Monte Carlo calculation of the integral of the expectation values using a sequence of random points *directly* obtained for instance from the `gasdev` subroutine (see previous Lectures). See for instance the code `direct_sampling.f90`. Study the numerical accuracy and the convergence of the previous quantities as a function of the number of sampling points.

(b) Is the normalization constant A of the wavefunction important for our purposes?

(c) *Metropolis sampling.* Repeat the sampling using the Metropolis algorithm. See for instance the code `metropolis_sampling.f90`. Evaluate the numerical accuracy and convergence of the more relevant quantities as a function of the number of sampling points.

3. **Correlations**

(a) Calculate the autocorrelation function $C(j) = \dfrac{\langle x_i x_{i+j} \rangle - \langle x_i \rangle^2}{\langle x_i^2 \rangle - \langle x_i \rangle^2}$ for a sequence or random numbers with a gaussian distribution using the Metropolis method, with different values of δ/σ: 1, 5, 10, 25, 50. Comment the results.

(b) For a fixed value of σ compare the autocorrelation function for two sequences of random numbers with a gaussian distribution (i) using the Metropolis method and (ii) using some ad-hoc routine, like for instance `gasdev` based on the Box-Muller algorithm. Discuss the results.

4. **Verification of the Boltzmann distribution**

We can verify directly that the Metropolis algorithm yields the Boltzmann distribution. We consider **a single classical particle** in one dimension in equilibrium with a heath bath (*canonical ensemble*). We fix therefore the temperature T, which labels a *macrostate*. The energy E can vary according to the particular *microstate* (in this particular case, it is enough to label a microstate, a part from the sign of the velocity).

(a) Write a code (see e.g. `boltzmann_metropolis.f90`) to determine the form of the probability distribution P(E) that is generated by the Metropolis algorithm. Let for instance *T=1*, the initial velocity *vinitial=0*, the number of Monte Carlo steps *nmcs=1000*, and the maximum variation of the velocity *dvmax=2*. Calculate the mean energy, the mean velocity, and the probability density P(E).

(b) Consider *ln P(E)* as a function of E. Can you recognize the expected behavior ? (see slides for the analytic derivation of P(E)) You should recognise that the asymptotic behavior is a straight line whose slope is $-1/T$.

(c) How many *nmcs* do you need to have a reasonable estimate of the mean energy and mean velocity ?

(d) Verify that your results do not depend from the initial conditions by changing *vinitial*. What does it change? What does it changes by changing instead *dvmax* ?

(e) Modify the program to simulate an ideal gas of **N particles** in one dimension. *[Hint: modify the subroutine Metropolis inserting a loop over the particles]* Consider for instance *N=20*, *T=100*, *nmcs=200*. Assume all particles to have the same initial velocity *vinitial=10*. Determine the value of *dvmax* so that the acceptance ratio is about 50% ? What are the mean energy $\langle E \rangle$ (i.e., total energy of the system $\langle E_{tot} \rangle$ divided by the number of particles) and the mean velocity? *[the symbol $\langle \rangle$ indicates temporal(statistical) averages]*

(f) Calculate P(E) (E now indicates the mean energy per particle), make a plot and describe its behaviour. Is it similar to the case N=1 ? Comment on that.

(g) Calculate the total energy E_{tot} for *T=10*, 20, 30, 90, 100, and 110, and estimate the heat capacity as the *numerical derivative of the energy with respect to the temperature, $C = \partial \langle E_{tot} \rangle / \partial T$. [C is the heat capacity, i.e. referred to the whole system; you may consider, alternatively, the specific heat, referred to a single particle...]*

(h) Calculate the mean square energy fluctuation $\langle \Delta E_{tot}^2 \rangle = \langle E_{tot}^2 \rangle - \langle E_{tot} \rangle^2$ for T=10 and T=40. Compare the magnitude of the ratio $C = \langle \Delta E_{tot}^2 \rangle / T^2$ numerically estimated from the mean square energy fluctuation with that obtained in (f).

5. **MC simulation of a simple N-particles model**

Consider an ideal gas of N non interacting, distinguishable particles, **confined** in a box (fixed **V**) and **isolated** (fixed **E**), divided into left/right with the possibility for one particle at a time to pass through the separation wall, with equal probability from the left to the right or viceversa.

A **macrostate** is specified for instance by the number of particles on the left side, say n, that can correspond to different **microstates** depending on the list of the specific particles there. A Monte Carlo approach consists in generating a certain number of movements, randomly, and consider them as representative of all the possible movements. The program `box.f90` is a possible implementation of the algorithm describing the time evolution of the system in terms of macrostates, i.e. –given an initial number of particles on the left, n– the approach to equilibrium and which is the equilibrium macrostate.

(a) Choose N=4, 10, 20, 40, 80, and n=N initially. Make a plot of n (or, better, of n/N) with respect to time. What is the equilibration time τ_{eq} (=how many MC steps)?

(b) Modify the program so that at each time step t it calculates the number of particles $< n(t) >$ averaged over different runs (e.g. 5 runs). Make a plot to compare $n(t)$ over the individual runs and averaged $< n(t) >$.

(c) *(Optional; do it at home!)* Compare the numerical value of $< n(t) >$ with the exact analytic results for a simple case, for instance N=4.

(d) *(Optional)* Consider only one run. Modify the program to calculate numerically the probability P_n of having *at equilibrium* a macrostate with n particles on the left, by simply counting the number of occurring microstates that correspond to the macrostate n and dividing for the total number of microstates generated in the time evolution. Plot the histogram P_n for N=20, 40, 80 and a "sufficiently" long run. Comment.

(e) Modify the program to measure the statistical fluctuations at the equilibrium, by calculating the variance $\sigma^2 =< n^2 > - < n >^2$, where the average is done over a time interval *after* reaching the equilibrium.

(f) Determine $< n >$ and $\sigma/ < n >$ at equilibrium for N=20, 40, 80. Which is the dependence of these quantities on N?
